BASAL METATARSAL OSTEOTOMY FOR HALLUX VALGUS

DAVID C. BORTON, MICHAEL M. STEPHENS

From St Mary's Orthopaedic Hospital and the Mater Misercordiae Hospital, Dublin, Republic of Ireland

We performed basal chevron metatarsal osteotomy on 32 feet (31 patients) for painful hallux valgus associated with an increased intermetatarsal 1/2 angle (> 12°). Pedobarographic and radiological examinations were done preoperatively and at a minimum of six months postoperatively.

The average hallux valgus angle was improved from 40.9° to 19.2° and the intermetatarsal 1/2 angle from 16.5° to 6.8°. The mean angle of declination of the first metatarsal was decreased by 1.4°.

The pedobarographs showed a significant reduction in areas sustaining pressure > 5 kg/cm², an increased total foot contact area and a higher percentage forefoot contact area on heel raise. There was a high level of patient satisfaction with relief of symptoms and improved appearance of the foot.

Received 29 July 1993; Accepted 28 September 1993

Metatarsus primus varus is associated with hallux valgus and there is a close relationship between the degree of the two deformities (Hardy and Clapham 1951, 1952; Bonney and Macnab 1952). There is, however, no agreement on which is the primary deformity (Piggott 1960; Kelikian 1965). Distal metatarsal osteotomy in patients with splayed feet has led to high rates of patient dissatisfaction (Hattrup and Johnson 1985; Meier and Kenzora 1985) and we believe that feet with an intermetatarsal 1/2 angle greater than 12° require a basal osteotomy.

PATIENTS AND METHODS

Between February 1991 and October 1992, 31 patients with painful hallux valgus and an intermetatarsal (IM) 1/2 angle > 12° (mean 16.5°) had pedobarographic and radiological assessment. There were 25 women (26 feet) and 6 men; their average age was 53.1 years (31 to 79). All had basal chevron metatarsal osteotomy.

Preoperatively, pain severity was documented by a visual analogue score graded from 0 to 10. Dorsoplantar and lateral weight-bearing radiographs were taken and pedobarographs, using the Musgrave foot print system (W. M. Automation, Carrickfergus, Co. Antrim, UK), were performed (Vaughan, Davies and O’Connor 1992).

The indication for surgery was painful hallux valgus which did not respond to conservative treatment. No patient had degenerative arthritis of the first metatarsophalangeal (MTP) joint. Simultaneous procedures were performed on the lesser toes in 15 feet. One patient had bilateral osteotomies performed with nine months between the procedures.

The average follow-up was 9.9 months (6 to 21). At the postoperative review patients were asked to grade their feet for overall satisfaction, pain and cosmesis. Satisfaction and pain were assessed using a visual analogue score graded from 0 to 10. Cosmesis was graded as either completely satisfied, satisfied with minor reservations or dissatisfied. Further dorsoplantar and lateral weight-bearing radiographs were obtained and from these the IM 1/2 angle, hallux valgus angle and angle of declination of the first metatarsal were measured and compared with the preoperative radiographs. Pedobarography was repeated (Holmes, Timmerman and Willits 1991), adjusting the stride length and stance width for each patient. Areas of pressure > 5 kg/cm², the total contact area, the forefoot contact area on heel raise and the centre of load were recorded and compared with those from preoperative pedobarographs.

Statistical analysis was done on a Macintosh Classic computer using the paired t-test on Datadesk 3.0 software (Odesta Corporation, Northbrook, Illinois). Operative technique. All the operations were performed under above-knee tourniquet after exsanguination. The first webspace is incised dorsally and the adductor tendon is released from the lateral sesamoid and the proximal phalynx. A dorsomedial incision is then made along the first metatarsal shaft avoiding the dorsal cutaneous nerve. The capsule of the MTP joint is incised longitudinally and the medial bony eminence resected from the metatarsal head using an oscillating saw. The bony exostosis is saved.
A 60° chevron osteotomy is fashioned with its apex 2 cm distal to the tarsometatarsal joint. The distal segment of the metatarsal is then planter flexed, displaced laterally and held by wedging bone from the exostosis into the dorsal limb of the chevron. This maintains plantar flexion and supination and distracts the upper limb of the chevron (Fig. 1). An absorbable suture is passed through the first metatarsal head and the second metatarsal neck and tied to secure the correction. The adductor hallucis is reattached to the first metatarsal neck and the capsule is closed after capsulectomy to tighten it and draw the sesamoids medially (Fig. 2). The skin is closed over a vacuum drain. Postoperatively, the foot is placed in a plaster boot, non-weight-bearing for two weeks. Partial weight-bearing is allowed for two weeks and then full weight-bearing for a further two weeks. At six weeks the cast is removed and radiographs are taken to confirm union.

RESULTS

Subjective evaluation. All but one of the patients were satisfied with the procedure; 14 were completely satisfied and 17 were satisfied with minor reservations. The one patient who was dissatisfied was a marathon runner who continued to have pain on running long distances. The mean satisfaction on the visual analogue score was 8.2±2.0. Five of the 15 patients who had had surgery on the lesser toes as well were completely satisfied with the
main operation but had minor reservations about stiffness in the lesser toes.

Pain was eased in all but one patient. Twenty-two feet were painfree and nine had occasional, minor pain. The pain scores improved from a mean of 4.7±2.2 preoperatively to a mean of 1.1±1.5 postoperatively. All but one of the patients were pleased with the cosmetic result; 23 were completely satisfied and 8 were satisfied with minor reservations. One patient developed hallux varus and although free from pain was dissatisfied with the appearance of the foot.

Radiography. The mean IM 1/2 angle improved from 16.5°±2.6° to 6.8°±3.2°, a mean correction of 9.7°. The hallux valgus angle improved from 40.9°±8.3° to 19.2°±9.4°, a mean correction of 21.7° (Fig. 3). The mean postoperative hallux valgus angles were calculated after excluding two patients who developed hallux varus of 13° and 27°. Their inclusion would have given an average
hallux valgus angle of 16.7° which would have been misleading. Sesamoid staging (Haines and McDougall 1954) improved from an average of 3 to 1.2. Preoperatively, the mean arch angle of the first metatarsal was 22.8°±3.1° and decreased to 21.4°±3.2° postoperatively, giving a mean decrease in the angle of declination of 1.4°. The osteotomies had all united by six weeks without problems.

**Pedobarography.** Preoperatively, the total contact area averaged 85.0 cm²±13.0 cm²; postoperatively, it increased by 14.2% to 97.1 cm²±13.9 cm² (Fig. 4; p < 0.001). The mean forefoot contact area on heel raise increased by 20.1% from 43.3 cm²±9.3 cm² to 52.0 cm²±9.1 cm² (Fig. 5; p < 0.001). Expressed as a percentage of total contact area this represents an increase from 50.6%±5.1% to 53.5%±4.3%, a mean increase of 5.7% (p < 0.01).

The average number of sensors measuring pressures > 5 kg/cm² was reduced from 6.1±4.1 to 4.4±3.2, a decrease of 27.9% (Fig. 6; p < 0.05). Preoperatively, the centre of load tended to lie laterally with loading during the propulsive phase through the third metatarsal head. Postoperatively, the centre of load was more medial with propulsive phase loading through the first interdigital cleft (Fig. 7).

**Complications.** No patient developed infection. Four have slight discomfort at the osteotomy site due to excess callus and two developed a hallux varus deformity, one of 13° and the other of 27°. The patient with the greater
deformity had no complaints while the other, although painfree, was dissatisfied with the cosmetic outcome.

DISCUSSION

Hallux valgus has been widely reported to be associated with metatarsus primus varus (Antrobus 1984; Kilmartin, Barrington and Wallace 1991) and there appears to be a close relationship between the extent of the two deformities (Hardy and Clapham 1951, 1952; Bonney and Macnab 1952). Debate remains whether metatarsus primus varus predisposes to or is a result of hallux valgus (Truslow 1925; Piggott 1960; Kelikian 1965). Most authors agree that patients with hallux valgus and a wide IM 1/2 angle require some procedure at the proximal metatarsal. Basal osteotomies of various kinds have been advocated; wedge excision (Lapidus 1934; Simmonds and Menelaus 1960; Golden 1961), crescentic (Mann and Coughlin 1986; Thordarson and Leventen 1992), and chevron (Corless 1976; Johnson, Cofield and Morrey 1979; Austin and Leventen 1981; Meier and Kenzora 1985; Richardson 1992). Some authors have favoured metatarsocuneiform arthrodesis (Myerson, Allon and McGarvey 1992) or a cuneiform osteotomy (Rocyn Jones 1948).

It has been shown that patients with varus deviation of the first metatarsal have first metatarsal pronation and that the degree of rotation is related to the IM 1/2 angle (Eustace et al 1993). These facts coupled with the problem of metatarsus elevatus (Thordarson and Leventen 1992) after basal osteotomy, suggest that it is necessary to supinate and to plantar flex the metatarsal at the site of the osteotomy. The bone wedge taken from the exostosis and placed in the dorsal limb of the chevron supinates, plantar flexes and distracts the distal metatarsal. Internal fixation is not required as the distraction of the upper limb of the chevron tightens the soft tissues and provides stability.

Basal chevron osteotomy, performed as we describe, has proved effective in relieving symptoms and in restoring feet to nearly normal shape and function.
