sufficient to relieve symptoms, but three or four injections at weekly intervals may be needed.

**Results.** These are shown in Table I. It is clear that in all cases the affected area is considerably reduced immediately after the injection and in all but two the effect persisted at follow-up, which was at 10 to 32 months (average 18 months). In 10 cases the area affected had been reduced to zero.

**Discussion.** Many surgeons still base their treatment of meralgia paraesthetica on the assumption that the causal lesion is a local one in the region of the inguinal ligament (Jones 1974). This assumption does not explain the association with spinal stenosis, nor the two tests we have described, nor the occasional bilateral case. Moreover, the considerable success obtained by epidural injection seems to us to justify the conclusion that, at least in some cases, the causal lesion is at L3/4.

**THE FLEXION SIGN OF NEEDLE PLACEMENT FOR HIP ARTHROGRAPHY: BRIEF REPORT**

ANTHONY A. BERNARD

Accurate needle placement is important in arthrography of the neonatal hip, but although various methods have been described, difficulties may occur. Ease of injection (Mitchell 1963) and re-aspiration of saline may be misleading, since they may be seen after extracapsular injection. The injection of a small amount of air (Crawford and Carothers 1982) or contrast medium, has been described but this may tend to obscure the subsequent images. There is also a small risk of air embolism (McCauley, Wunderlich and Zimblor 1981). Aspiration of synovial fluid or joint contents is only effective when the joint contains sufficient fluid. A "waggle" sign and suction artrography have recently been described (Lancaster and Cummings 1987), but this deviation of the needle is caused by hip rotation, and carries some danger of intra-articular damage.

**Technique.** The technique described in this paper was used for hip arthrography in 60 cases, 42 of them for congenital dislocation. The child is anaesthetised, placed supine on a radiolucent table and the area cleaned and draped. A short-bevelled, 18-gauge spinal needle with the stylet in place is inserted, in the neonate, two fingerbreadths distal and two fingerbreadths medial to the anterior superior iliac spine. The femoral artery is palpated and the tip of the needle is directed deep to it into the anterior aspect of the capsule of the hip. A giving-way sensation is usually felt as the needle punctures the capsule.

A fluoroscopic check is made to ensure that the tip of the needle is opposite the middle of the femoral neck and not in the region of the limbus, where clear visualisation is needed. The stylet is then removed and 5 to 10 ml of saline are injected from a 20 ml syringe. As the joint is distended, the lower limb is seen to move into a few degrees of flexion and lateral rotation. When the syringe is removed from the hub of the needle, saline will squirt out under pressure as the limb returns to its original position. Injection of contrast medium is then carried out.

**Discussion.** The flexion and lateral rotation of the limb produced by stretching of the capsule on distension are caused by the orientation of its fibres in a spiral fashion. Distension of the hip causes it to move into a position that maximises the joint capacity by "unwinding" the capsule.

The flexion sign was seen to be positive in all normal or subluxated hips, but was less marked in grossly displaced hips. In these cases the diagnosis was clinically obvious, and placement of the needle into the empty acetabulum was easily accomplished. No complications have arisen from this simple method of ensuring accurate placement of the needle.
