MYCOBACTERIUM AVIUM INTRACELLULARE INFECTION OF HIP ARTHROPLASTIES IN AN AIDS PATIENT

JEFFREY R. McLAUGHLIN, MAUREEN TIERNEY, WILLIAM H. HARRIS

Mycobacterium avium intracellulare (MAI) is rarely a human pathogen, but there has been a sharp increase in the incidence of atypical mycobacterial infections in association with AIDS (Hoy et al 1990; Horsburgh 1991), with reports of cardiac, gastrointestinal and respiratory infections (Packer, Cesario and Williams 1988). A literature search revealed no reported case of MAI infection in total hip arthroplasty.

Case report. A 20-year-old man with severe bilateral osteoarthritis of the hips secondary to Perthes’ disease had a cemented right replacement with trochanteric osteotomy in 1972 and a similar operation on the left in 1973. By 1980, he had asymptomatic loosening of both components on the left and had a cemented revision.

He became HIV-positive in 1988, and in August 1991 developed Pneumocystis pneumonia and was diagnosed as having AIDS. He was treated with AZT, trimethoprim, sulphamethoxazole and acyclovir and remained well until April 1992, when he developed increasing pain in both hips, only being able to walk less than two blocks even with crutches. He had no skin lesions and his surgical scars remained well healed. Radiographs showed loosening of both acetabular components with surrounding lysis (Fig. 1). There was also some lysis about both femoral components.

In April 1992, hip aspirations revealed Mycobacterium avium intracellulare in both hips and his blood cultures were also positive for MAI. Treatment was with four oral antibiotics: ciprofloxacin 750 mg and clarithromycin 500 mg each twice daily, and rifampicin 600 mg and cefazolin 100 mg each four times daily, in addition to his AZT, trimethoprim and sulphamethoxazole and acyclovir.

In June 1992, at resection arthroplasty of the right hip, the acetabular component was grossly loose but the femoral component was well fixed. There was marked wear of the polyethylene liner. Vancomycin was added to his drugs after aerobic, anaerobic, mycobacterial and fungal cultures had been obtained, and a Hickman catheter placed.

Histological examination of operative specimens showed clusters of acid-fast bacilli in necrotic tissue with minimal inflammatory response (Fig. 2). The specimens grew MAI and a very rare coagulase-negative staphylococcus on one culture, and one colony only of staphylococcus on another. Because of pyrexia after operation, ethambutol was added to his antibiotics and the dose of clarithromycin was increased to 1 g twice daily.

Bed rest with the involved leg in balanced suspension continued for six weeks, after which the Hickman catheter was removed and he was mobilised on two crutches.

The patient was discharged to his home 45 days after admission, on nine oral antimicrobial drugs, four AIDS drugs and warfarin for a deep femoral vein thrombosis detected by ultrasound. He died five months later.

Discussion. Mycobacterium avium intracellulare is a ubiquitous organism found in soil, food and water (Ellner, Goldberger and Parenti 1991). MAI infections are rare and usually occur in elderly patients with chronic lung disease or patients who are immunocompromised. Before 1980 only 24 cases of disseminated MAI infections had been reported (Horsburgh 1991), but recently there has been a marked increase in both Mycobacterium tuberculosis and atypical mycobacterial infections in AIDS patients. MAI infections are reported to occur in 15% to 24% of patients with AIDS (Hawkins et al 1985; Bessesen et al 1990; Hoy et al 1990) and 53% of AIDS patients who died at the Memorial Sloan Kettering Cancer Center were found at post-mortem to have disseminated MAI infection (Hawkins et al 1985); similar findings have been reported by Wallace and Hannah (1988).

MAI can usually be isolated and identified using media generally available in clinical microbiology laboratories. The acid-fast bacilli are readily seen on Ziehl-Nielsen (Horsburgh 1991) or auramine O fluorochrome (Hawkins et al 1985) stains. Cultures of blood, urine, sputum and stool are generally inoculated on to Middlebrook 7H11 agar or Loewenstein-Jensen media (Hawkins et al 1985). Colonies grow in 7 to 51 days (Macher et al 1983; Pierce, De Young and Roberts 1983). Histological examination shows numerous acid-fast bacilli within distended histiocytes. Granulomas are poorly formed and the host inflammatory response is minimal (Horsburgh 1991).

Infections with MAI are characterised by host colonisation predominantly through the respiratory or gastrointestinal tracts, which is followed by haematogenous dissemination. This contrasts with Mycobacterium tuberculosis infections, in which dissemination usually occurs after the reactivation of quiescent disease (Horsburgh 1991).

Disseminated MAI infection causes fever, malaise, weight loss and anaemia, while abdominal pain and diarrhoea are common. Pneumonia is less frequent but may occur (Hawkins et al 1985; Horsburgh 1991). Most organ systems may be involved, however, and musculo-skeletal infections involving the wrist, distal ulna, flexor tendon sheath, and knee have been reported (Pedersen, Hald and Saxegaard 1988; Rolfe and Sowa 1990; Stark 1990; Whitaker et al 1991).

In one series, blood cultures were positive in 98% of patients with MAI, with cultures of lymph nodes and bone-marrow aspirates positive in 100% (Hawkins et al 1985).

Until recently antibiotics for MAI infection in AIDS had little success, but more aggressive multiple drug regimens have given more promising results. Hoy et al (1990) reported decreased symptoms in 18 of 25 patients, with clearing of bacteraemia in 22 after the use of ethambutol, rifabutin, clofazimine andisoniazid. Chiu et al (1990) had similar success with ethambutol, rifampicin, ciprofloxacin and amikacin. The new macrolide anti-biotics, clarithromycin and azithromycin (Young et al 1991; de Lalla et al 1992), have impressive in vitro activity against MAI, and the use of these drugs in combination with other agents has had promising results (Young et al 1991; de Lalla et al 1992). At present the recommended therapy is four drugs, usually including rifampicin or rifabutin, a new macrolide, and ciprofloxacin.

Neither the effectiveness nor the duration of antibiotic treatment for disseminated MAI infection has been established. We consider that a total joint arthroplasty infected with MAI in a patient with AIDS should be removed and that a prolonged course of antibiotics should be given. In patients with AIDS, MAI infections produce persistent bacteraemia, and reimplantation of an arthroplasty therefore carries an increased risk. Even if infection can be cleared, reconstruction is probably not indicated in patients severely debilitated by AIDS.
