We examined whether somatosensory evoked potentials (SEPs) were detectable after direct electrical stimulation of injured, reconstructed and normal anterior cruciate ligaments (ACL) during arthroscopy under general anaesthesia. We investigated the position sense of the knee before and after reconstruction and the correlation between the SEP and instability.

We found detectable SEPs in all ligaments which had been reconstructed with autogenous semitendinosus and gracilis tendons over the past 18 months as well as in all cases of the normal group. The SEP was detectable in only 15 out of 32 cases in the injured group, although the voltages in the injured group were significantly lower than those of the controls. This was not the case in the reconstructed group. The postoperative position sense in 17 knees improved significantly, but there was no correlation between it and the voltage. The voltage of stable knees was significantly higher than that of the unstable joints. Our findings showed that sensory reinnervation occurred in the reconstructed human ACL and was closely related to the function of the knee.

Received 15 June 1998; Accepted after revision 18 January 1999

The incidence of injury to the anterior cruciate ligament (ACL) during sport has increased. It is estimated that in the USA 95 000 patients sustain such an injury each year of whom 50 000 require reconstruction.1,2 About 2000 articles on the ACL have been published.3 It functions, along with other anatomical structures around the knee, to maintain static and dynamic equilibrium and it has an important role in proprioceptive feedback. Orthopaedic surgeons have focused mainly on how to reconstruct the ligament. Recently, it has been demonstrated histologically that there are several types of mechanoreceptor in the human ACL.4-8 Neural elements comprise approximately 1% of the area.9 These mechanoreceptors such as Pacinian corpuscles and Ruffini endings are thought to contribute to the position sense of the joint by feedback and reflex muscular activity.10-15

Using an electrophysiological technique in nine patients, Pitman et al16 demonstrated that cortical somatosensory evoked potentials (SEPs) could be recorded after direct electrical stimulation of the normal ACL. These are elicited by electrical or mechanical stimulation to peripheral nerves and also allow assessment of the entire length of the somatosensory pathway from the peripheral nerve to the cerebral cortex including the posterior columns of the spinal cord. They concluded that their results provided direct evidence of the presence of a proprioceptive function in the intact ACL. Valeriani et al17 reported that seven of ten patients with a decreased position sense due to ACL insufficiency presented loss of the cortical P27 potential which reflects proprioceptive different inputs from the knee after stimulation of the common peroneal nerve above the articular nerve serving the ACL.

Our aim was to examine whether cortical SEPs are detectable after direct electrical stimulation of the injured or the reconstructed ACL. We compared the shape of the SEP with that from the normal ACL and examined the correlation between it and the instability and position sense of the injured and reconstructed knees.

 Patients and Methods

Between January 1997 and March 1998, we studied 73 knees in 73 patients who had given informed consent to undergo intraoperative monitoring of the SEP. Four patients were excluded from analysis of the results because of technical problems. The remaining 69 patients were divided into three groups: the ACL-deficient group (32), the ACL-reconstructed group (23) and the control group (14) (Table I). In the ACL-deficient group the ligament had been ruptured but the remnants were seen to bridge the femur and tibia although the sites of attachment were not anatom-
ical and the diameter of the tissue was small. The reconstruction group had received doubled semitendinosus and gracilis tendons in 22 knees and allogeneic fascia lata in one. They were examined at a minimum of 18 months after reconstruction. The control group with a normal ACL had had arthroscopy for internal derangement of the knee without abnormality in five knees, for meniscal injury in five and for a superficial chondral lesion in four.

Before arthroscopy, laxity was measured using the KT-2000 knee arthrometer (MED Metric Corporation, San Diego, California) with a force of 133 N applied with the knee flexed at 30°. Both knees were tested and the laxity recorded as the difference in millimetres. The other knee was always normal. The position sense of the knee was tested to examine the ability of the patients to restore an angle at which the joint had been placed previously; this test was then modified according to the technique of Skinner et al. The examiner extended one of the patients’ legs at a slow steady rate of approximately 10° from a starting angle of 90°. The leg was stopped at a random angle of between 5° and 25° and held by the examiner for three seconds. The knee was then returned to the starting angle, and the examiner asked the subject to return the leg to the previous position. Inaccuracy was recorded as the difference between the perceived angle and the actual angle of flexion. Both knees were measured ten times and the mean inaccuracy was expressed as the error for the operated knee minus that recorded for the normal side.

### Somatosensory evoked potentials

The patients were anaesthetised using nitrous oxide, oxygen and fentanyl citrate (0.1 ml/kg). Inhalation anaesthetic agents such as halothane, isofluorane and enflurene were not used because of their depressive effects on cortical responses. No local anaesthesia or epinephrine was used.

The ACL was electrically stimulated using a bipolar electrode probe with a Teflon-coated tip (AU-1, Inter-Medical Co Ltd, Tokyo, Japan) inserted into the midportion through an anteromedial portal. The stimulus comes only from the extreme tip of the probe and does not spread through the synovial fluid or physiological saline to other structures of the knee.

The stimulus used was a square wave of 0.2 ms duration at an intensity of 10 mA and rate of 3/s. Electrode impedance was maintained at between 2 and 10kΩ. Room temperature was maintained between 23 and 25°C. The cortical response was recorded over a bandwidth of 0.5 to 1500 Hz for a duration of 100 ms. Two hundred epochs were averaged; two responses were recorded for each trial and superimposed to ensure consistency with a measurement system for evoked potentials (Synax 1100; NEC Medical Systems, Tokyo, Japan).

The SEP was monitored by a surface electrode placed on the scalp at a point 2 cm lateral and 2 cm posterior to the CZ position according to the international 10 to 20 system with reference to the FP and ear. The ACL was electrically stimulated by a bipolar electrode probe. A peak or trough in each SEP (usually P1 trough or N1 peak) was chosen as the feature for programmed automatic detection for a monitoring session. In addition, SEPs produced by stimulating the posterior cruciate ligament (PCL) were recorded under the same conditions. The values of the latency and potential of P1 and N1 induced by PCL electrical stimulation were referred to as the control. The latency of P1 and N1 and the difference of potentials between P1 and N1 were calculated as the voltage of the SEP. The ratio of the voltage of the SEP induced by stimulation of the ACL to that induced by stimulation of the PCL was calculated. To determine the reproducibility of the SEPs the recording was repeated at least twice. The higher voltage was selected as being the most representative.

### Statistical analysis

All numerical data were expressed as the mean ± so. Differences in parameters such as the latency and potential of P1 and N1, and the voltage ratio between the three groups were assessed using one-way analysis of variance. If a statistical difference existed, Scheffe’s post-hoc test was used. The degree of correlation between the potential of the SEP, instability and position sense were estimated using Pearson’s correlation coefficient (r). Student’s unpaired t-test was used to compare the voltage between the stable knees and the unstable knees in the reconstructed group and the paired t-test to compare the position sense after operation with that before. A p value of less than 0.05 was regarded as statistically significant.

### Results

#### SEP induced by electrical stimulation of the ACL

In the ACL-deficient group, reproducible cortical SEPs were detected only in 15 out of 32 knees and in the reconstruction group in 22 out of 23 knees (Fig. 1). The one patient in whom an SEP was not detected had an allograft 18 months previously. In the control group, reproducible SEPs were detected in all 14 knees.

Table II shows the data on the P1 and N1 latency and the voltage of the SEP obtained after stimulation of the ACL and PCL. The voltage of the SEP in the ACL-deficient group was significantly greater than in the control and reconstructed groups (Table II, Figs. 2–3).

The mean side-to-side difference of anterior displacement as measured by the KT-2000 knee arthrometer in the three groups was 5.33 ± 2.04 mm, 2.18 ± 2.27 mm and 0.89 ± 2.25 mm, respectively. The difference in the ACL-deficient group was significantly larger than that of the remaining two groups. There was no significant difference between the reconstructed and the control groups. There was a significant inverse correlation between the voltage of the SEP from the ACL and the side-to-side difference of anterior displacement in the deficient and reconstructed groups (Fig. 2). In the reconstructed group, the voltage of the SEP in the control knees with a side-to-side difference of anterior displacement of less than 3 mm was significantly higher than that in the unstable knees (8 knees) with a side-to-side difference of 3 mm or more (p = 0.035) (Fig. 3).

### Joint position sense

The mean inaccuracy of the joint position sense was 1.01 ± 1.24° in the ACL-deficient group, 0.57 ± 1.53° in the reconstructed group, and 0.19 ± 0.87° in the control group. The inaccuracy of the ACL-deficient group was significantly higher than that of the other two groups. There was no significant difference in the values between the reconstructed and the control groups. In 17 knees in which the joint position sense was examined before and after operation, the preoperative inaccuracy was 2.15 ± 1.45° which improved significantly to 0.58 ± 1.68° (p < 0.01) after operation. Fourteen of 17 knees showed an improvement in joint position sense after reconstruction. In both the deficient and the reconstructed groups the larger inaccuracy of the joint position sense, the lower was the voltage from the ACL, but this was not statistically significant (Fig. 4).

Cortical SEP of a 20-year-old girl whose left ACL had been reconstructed 24 months before. Reproducible SEPs had been established with a trough (P1) and a peak (N1) in the initial component of the response. Although the voltages between P1 and N1 are 1.22V and 1.19V, the higher voltage of 1.22V is selected as the representative one.
Ruffini and Golgi receptors are thought to be slow-adapting mechanoreceptors such as Ruffini endings, the Golgi tendon organ, and the Pacinian corpuscle in the ACL. They showed that afferent nerve fibres from the ACL are activated by local pressure to the ligament or by certain movements of the knee, suggesting that mechanoreceptors provide information about tension of the ACL. Barrack et al examined the proprioceptive function of the knee in patients with injury to the ACL and concluded that poor results of proprioception were attributable to the loss of the ACL rather than other variables.

Our results clearly showed poor joint position sense and a low incidence of positive SEPs in the ACL-deficient group and, by contrast, an improvement of joint position sense and the positive potential in all but one knee after reconstruction, indicating that there may be a correlation between them.

Barrett examined proprioception in 45 patients after reconstruction of the ACL and showed that although their proprioceptive function was improved it was still inferior to that of normal patients. Co et al supported these findings. In dogs Barrack et al showed that the SEP returned in two out of six animals and that the free patellar graft contained neural elements six months after reconstruction of the ACL.

The position sense of the knee cannot be examined in animal studies but measurement of the SEP and the improvement in position sense are demonstrable in human studies. The return of sensory neurones in the ACL cannot be examined owing to lack of biopsied tissue. There have been no reports on the SEP after direct stimulation of the reconstructed ACL in clinical cases.

Our study showed that sensory reinervation occurs in the reconstructed ACL and that voltage of the SEP inversely correlates with the degree of instability. Reconstruction of the ACL is not only reconstruction of a mechanical restraint but also of knee function.
